Goal

Create a software tool to aid in the construction of optimal colormaps for viewing and labeling brain anatomical images.

Background

The application of color is an indispensable means of visually distinguishing anatomical regions of the brain [1,2]. The need to facilitate visualization of brain images has become particularly urgent with the inception of large-scale anatomical labeling projects, such as the BrainCOLOR project, in which hundreds of MR images of the human brain are being manually labeled (www.braincolor.org/protocols) as well as viewed online (www.braincolor.org/roygbiv).

Choosing a color space

Our colormap must consist of colors that are perceptually distinct, so it is reasonable to choose a color space that is perceptually uniform, where a separation between two colors in the color space is as discriminable as the same separation between two other colors in the color space. The International Commission on Illumination (CIE) devised a color space in 1931 that facilitates color description (Fig.1). Subsequent improvements led to the CIELAB and CIEUV color spaces, as well as a cylindrical variant, CIELCh, all of which attempt to be perceptually uniform.

Constructing a colormap

We uniformly sampled hues from the CIELCh cylinder (Fig.2) at different distances from the center (70-100% chrominance) and at different lightness values. The resulting colormap (Fig.3) has the same number of colors as regions we wish to color (49 cortical regions in the BrainCOLOR protocol). We intend to expand the number of colors to include subcortical and other regions.

Maximizing discriminability of adjacent regions

To easily distinguish brain regions from each other, we wish to maximize the color difference between adjacent regions. We do this by constructing a graph that represents connections (edges) between regions (nodes).

We define an *optimal mapping* of colors as the combination of colors assigned to nodes with the maximum sum of color differences between connected nodes, defined by the CIE2000 Delta E measure (http://en.wikipedia.org/wiki/Color_difference).

However, we cannot compute 8.8×10^{18} permutations of the 49 colors in the colormap, so we break up the brain into sublobes and compute the permutations of portions of the colormap at a time:

Grouping regions by using similar colors

For labeling a brain image, maximum discriminability is paramount. For viewing a brain image, however, it is useful to visually group regions by assigning similar colors to the regions within a group. To create this visual grouping, we colored each subgraph with a neighborhood of colors (sampled within a wedge of the CIELCh cylinder).

Conclusion and Future Work

We have created Python software for creating and applying colormaps to brain images.

Download the software from: <http://binarybottle.github.com/brainCOLORMap>

The software calls the Python libraries: *NumPy*, *NetworkX*, *Python-ColorMath*, *Matplotlib*, and *xird*, to:

1. convert a table of adjacent regions (an adjacency matrix) to a weighted graph of colored nodes
2. compute permutations of colors for each subgraph to optimally distinguish colors of adjacent regions
3. apply similar colors to predefined groups of regions

There are many improvements we could pursue. We have targeted the following for future work:

- ➔ Develop an optimization algorithm for whole graphs or larger subgraphs.
- ➔ Restrict the color space to colors that can be displayed; currently, the CIELCh colors that should appear different from one another may appear similar after conversion to sRGB colors.
- ➔ Seed color values to better control the range of colors for each group of regions.
- ➔ Accommodate visual concerns such as color blindness by adapting the colormap accordingly.

This project is funded as part of NIMH R01 MH084029-02 and NIMH R43 MH084358.

- >16,000 registrations
- 80 manually labeled brain images for evaluation
- 2 different brain labeling protocols

Volume and surface data
(labeled in volumes *and* surfaces)

registrations

Tests 1-4

Test 5: resampling

Test 5: resampling

1. Brain extraction aids volume registration.
2. Custom templates improve registration over direct pairwise registration.
3. Resampling volume labels on surfaces *or* surface labels on volumes precludes a fair comparison between surface and volume registration methods.

Recommendation:

Construct a custom template from a limited sample drawn from the same or a similar representative population, using the same algorithm used for registering brains to the template.

Match the features across brains

Combine features across modalities

A gray/white matter surface (left lateral view) with visible sulcal pits highlighted (cyan circles). These features go by different names (sulcal roots, buried or annectant gyrii, plis de passage) and may be well conserved structures formed early in development.

DTI connectivity graph (same subject). Vertices represent all extracted sulcal pits and each edge width indicates a connection probability greater than 0.01 between two vertices (and does not follow a tractography path).

Match “brain graphs”

Early attempt at subgraph extraction (upper row) and matching (lower row).
These graphs were constructed from (left to right) a remitter, non-remitter, and control subject.
The subgraphs in red in the lower row have the highest small-worldness ratio.

Characterize anatomical variability

Example of natural morphological variability: left inferior parietal lobule (IPL; Kiriya et al. 2009).

(A-D) are MRI data and (E-G) are post-mortem specimens.

(A) IPL is highlighted and folds are outlined.

(B,E) Typical folding pattern.

(C,F) PreSMG pattern: an additional gyrus (ellipse) lies between postCS and SMG.

(D,G) PreAG pattern: an additional gyrus (ellipse) lies between SMG and AG.

[SMG: supramarginal gyrus; AG: angular gyrus; postCS: postcentral sulcus; IPS: intraparietal sulcus; Sy: Sylvian fissure, STS: superior temporal sulcus; *sulcus intermedius primus]
